The proton-dripline nucleus ^{17}Ne is one of the candidates for a simultaneous 2p-emitter, since the rst excited state of ^{17}Ne is bound with respect to one proton emission and unbound with respect to two proton emission. This decay-mode is in direct competition with the γ-decay back to the ground state in ^{17}Ne. The latest results from the measurement of the γ-decay branch (see e.g. ref. [1]) leave room for the existence of a 2p-branch. The experiment to search for the 2p-branch was performed at the NSCL and is described in detail in the last annual report [2], including the description of the multi-stage particle telescope.

The energy calibration for the reaction products was performed using ^{15}O beams and proton beams with different energies. For the calibration the multi-stage particle telescope and the target were in the same conguration as during the real experiment. The A1200 fragment separator was operated without a degrader, so that many other fragments produced from the primary beam ^{20}Ne down to ^{12}C reached our detector setup. These were used as an additional check of the calibration.

To identify the incoming particle we used the TOF (g 1a), between a plastic scintillator (45m upstream) and the Si-PIN-detector. Additional separation was achieved after the bending magnet at the end of the Wien-lter where the secondary ^{17}Ne beam was spatially separated from the biggest contaminant ^{1}5O [2]. A geometrical gate was set on the 40x40 strip detector as shown in (g 1b). An algorithm was developed to extract the particle trajectories from the hit pattern in the segmented detectors.

Fig2a. shows the ΔE(PIN)-E(Si5) spectrum gated on incoming ^{1}7Ne. One can clearly see the ^{1}7Ne peak and also channeling events in the 5mm thick Si-detector (Si5) or in the PIN-detector. Under the ^{1}7Ne peak is a small enhancement corresponding to ^{1}5O fragments from the (^{1}7Ne, ^{1}5O) reaction. A gate on events in coincidence with two protons cleans up the spectrum and two peaks are visible (g.2b). One corresponds to ^{1}7Ne, which goes through the ΔE-detectors as ^{1}7Ne and breaks up into ^{1}5O and two protons in Si5. So these events have the same ΔE as incoming ^{1}7Ne but less energy is deposited in Si5. The

other peak corresponds to events where ^{1}7Ne breaks up in ^{1}5O and two protons in the target, including the candidates for the di-proton decay mode.

In g. 3 the sum of the ΔE in all the strips of the 16x16 detector is plotted against the sum of the deposited energy in all CsI detectors. In a spectrum gated on incoming ^{1}7Ne (g. 3a) the p- and d-bands can be seen. A bright band, for events with twice the ΔE and E of the protons can be identied with the 2p-band. At even larger energy-losses and energies one can see also the ^{3}He and ^{4}He bands. If one applies an additional condition for two-particle events, where the 16x16 strip detector was hit by two particles in different pixels, the spectrum is dominated by the 2p-band (g 3b).

After removal of remaining background, the next step in the analysis will be the transformation of the four-momenta of the ejectiles into the center of mass system using the reconstructed trajectories of the whole reaction. This will lead to the excitation energy of the events, which is required to answer the question of a possible di-proton decay of ^{17}Ne.
